How Pydantic validation works:
Pydantic checks that the data matches the types and rules we define in our models. For example, it ensures fields like gender, price, and product_name are not empty and that price and quantity are positive. If the data doesn't meet the rules, Pydantic raises a clear validation error before we process it.

Benefits of validation:
It catches bad data early, so we don't send invalid products to the API. It also guarantees that both input and output are in a consistent format, making downstream processing much safer and easier.

Challenges you faced:
Interestingly, the validation didn't find any invalid products in the dataset, which seemed a bit surprising. Also, making sure the API output matches the expected JSON format required an extra Pydantic model for the listings.

Improvements you made:
We added full validation for all key product fields (gender, masterCategory, subCategory, articleType, baseColour, season, usage, product_name) and validated the API-generated JSON too. On top of that, we improved the prompt to include all relevant fields for better SEO in the generated listings.
